## Abbreviations

ENNC	enhanced normalized normal constraint.
MOO	multiobjective optimization.
MOOP	multiobjective optimization problem.
NBI	normal boundary intersection.
NNC	normalized normal constraint.
PID	proportional integral derivative.
WS	weighted sum.

# Chapter 1

## Introduction

The design of control systems always has to consider multiple and possibly conflicting design objectives. Under this perspective, the task of the engineer in charge of the control system, becomes to find the optimal point of compromise within this set of distinct objectives (Garpinger, Hägglund, and Åström 2012).

The most used control algorithm in industry is the proportional integral derivative (PID). This type of algorithm is used in a wide variety of applications, due to its limited number of parameters, its ease of implementation and its robustness (Åström and Hägglund 2005) and represents an area of active study since the first tuning methodology was proposed in the 1940s (Ziegler and Nichols 1942). In the case of this particular project, in order to have a direct impact on the industry and the research community in process control systems, it will focus on the problem of the tuning of the parameters of controllers PID.

It is common that the problem of tuning the parameters of industrial controllers is posed as an optimization problem. When all the objectives need to be taken into account at the same time, this problem becomes a multivariate multiobjective optimization problem. In the particular case of industrial PID controllers, this problem is also non-linear and (possibly) non convex, therefore, the problem at hand is not trivial.

Regardless of the methodology to be used, it is generally computationally expensive to solve a multiobjective optimization problem, which can lead to a scenario of multiple solutions equally optimal, so that in addition to solving the optimization problem, the control engineer, ends up with the extra responsibility of entering into a decision phase a posteriori to finally choose the best set of parameters for its specific application.

In this sense, multiobjective optimization (MOO) tuning of PID controllers remains as an open research subject, even though it has been studied for several decades. For example, in (Seaman, Desrochers, and List 1994) a type of MOO is used to tune PID controllers in a plastic injection molding process. In (Abbas and Sawyer 1995), an algorithm based on several optimizations is proposed to find the optimal parameters of a PID controller; this algorithm took into account several variables such as stationary error, rise time, overrun, settling time and maximum

controller output within the feedback loop. More recently, bio-inspired techniques such as neural networks, fuzzy logic or genetic algorithms have been used to solve the optimization problem (Reynoso-Meza et al. 2013). In (Bagis 2011), A Tabu search algorithm is used to tune PID controllers in real time, based in a set of closed loop specifications and a cost function. In (Chiha, Liouane, and Borne 2012) the multiobjective optimization problem (MOOP) for PID controllers is solved using the ant colony approach, this methodology tries to simulate the behavior of real ants when they are looking of the shortest path to a given objective.

Beside bio-inspired methods for MOOP, there are several methodologies that transform the MOOP into a single function optimization problem, by rewriting the problem with extra constraints. The simplest method is the weighted sum (WS) (R.T. Marler and J.S. Arora 2004). With the WS method, the multiobjective cost function is transform in a one dimensional function using a weighted sum that give a greater relative weight to a function in comparison to the others. For each set of weight values a different optimal solution is found for the same problem. The set of all solutions is part of the Pareto front (R.T. Marler and J.S. Arora 2004). The Pareto front corresponds to all equally optimal solutions for a MOOP. The problem with the WS method is that, although the results obtained are from the Pareto front, it is not possible to satisfactorily construct the entire front (Das and Dennis 1997; Achille Messac, Puemi-Sukam, and Melachrinoudis 2000; R. Marler and Jasbir Arora 2010).

In order to obtain the Pareto front correctly, other methodologies have emerged that surpass the WS. The normal boundary intersection (NBI) method (Das and Dennis 1998) consist in rewriting the optimization problem so that the feasible area is shortened by an equality constraint that depends on an extra parameter. The solution of this new problem will terminate at the Pareto border and by varying this extra parameter, it is possible to find the Pareto front so that each found point is equally spaced at the front. This feature is very useful since it gives an overall idea of the shape of the front. NBI has been applied to the tuning of controllers in (Gambier 2009) where the controller is selected taking into account different performance indexes like the integral of the squared error (ISE), the integral time-weighted squared error (ITSE) and the integral of the squared time-weighted squared error (ISTSE). Other methodology similar to NBI is the normalized normal constraint (NNC) (A. Messac, Ismail-Yahaya, and Mattson 2003), which converts the MOOP in a single function optimization with an extra inequality constraint.

It should be noted that these methodologies have also been used in other areas apart from the control of industrial processes. A few examples of the areas in which it has been applied are: calculation of optimal power flow in power systems (Roman and Rosehart 2006) and distributed generation planning (Zangeneh and Jadid 2007), for the control of biochemical processes (Logist, Erdegheem, and Impe 2009), circuit analysis (Stehr, Graeb, and Antreich 2003), development of optimal supply strategies for the participants of oligopolistic energy markets (Vahidinasab and Jadid 2010).

Although in the area of process control, there are examples of the use of these algorithms (Gambier 2009), they do not take into account the different sources of disturbance to the system, but are different measures of performance to the same

source of disturbance (the change in reference), and using a simple PID controller of a single degree of freedom.
